# Introduction to High Performance Computing WI4049TU

# Lab Report

Author: Elias Wachmann (6300421)

December 6, 2024

# General Remarks

This final Lab report includes the answers for the exercises (base grad denoted in paranthesis):

- 0. Introductory exercise (0.5)
- 1. Poisson solver (1.75)
- 2. Finite elements simulation (1.0)
- 3. Eigenvalue solution by Power Method on GPU (1.75)

The optional **shining points** (e.g., performance analysis, optimization, discussion, and clarifying figures) which yield further points are usually marked by a small blue heading in the text or an additional note is added under a figure or table. For example:

This is a shining point.

# 0 Introductory exercise

In the introductory lab session, we are taking a look at some basic features of MPI. We start out very simple with a hello world program on two nodes.

#### Hello World

```
#include "mpi.h"
#include <stdio.h>

int np, rank;

int main(int argc, char **argv)

{
    MPI_Init(&argc, &argv);
    MPI_Comm_size(MPI_COMM_WORLD, &np);
    MPI_Comm_rank(MPI_COMM_WORLD, &rank);

printf("Node %d of %d says: Hello world!\n", rank, np);

MPI_Finalize();
return 0;

}
```

This program can be compiled with the following command:

```
mpicc -o helloworld1.out helloworld1.c
```

And run with:

```
srun -n 2 -c 4 --mem-per-cpu=1GB ./helloworld1.out
```

We get the following output:

```
Node 0 of 2 says: Hello world!
Node 1 of 2 says: Hello world!
```

From now on I'll skip the compilation and only mention on how many nodes the program is run and what the output is / interpretation of the output.

#### 0.a) Ping Pong

I used the template to check how long MPI\_Send and MPI\_Recv take. The code can be found in the appendix for this section.

I've modified the printing a bit to make it easier to gather the information. Then I piped the program output into a textfile for further processing in python. I ran it first on one and then on two nodes as specified in the

assignment sheet. Opposed to the averaging over 5 send / receive pairs, I've done 1000 pairs. Furthmore I reran the whole programm 5 times to gather more data. All this data is shown in the following graph:

Figure 1: Ping Pong: Number of bytes sent vs. average time taken from 1000 pairs of send / receive. 5 runs shown for each size as scatter plot. Mean of these 5 runs shown as line. Blue small fit includes all data points up to 131072 bytes, blue large from there. Red small fit includes all data points up to 32768 bytes, red large from there.

As can be seen in the data and the fits, there are outliers especially for the larger data sizes. For our runs we get the following fits and Rš values:

Run Type	Data Size Fit Equation		Rš Value
Single Node	Small (<=131072)	$5.95 \times 10^{-7} \cdot x + 7.97 \times 10^{-4}$	0.92
Single Node	Large ( $>= 131072$ )	$4.61 \times 10^{-7} \cdot x + 1.23 \times 10^{-2}$	0.89
Two Node	Small (<=32768)	$1.07 \times 10^{-6} \cdot x + 2.60 \times 10^{-3}$	0.97
Two Node	Large (>= $32768$ )	$4.41 \times 10^{-7} \cdot x + 3.42 \times 10^{-3}$	0.97

Table 1: Fit Equations and Rš Values for Single Node and Two Node Runs

**Note:** Each run was performed 5 times (for 1 and 2 nodes) to get a fit on the data and calculate a Rš value. TODO: **Further analysis needed?** 

#### Extra: Ping Pong with MPI\_SendRecv

We do the same analysis for the changed program utilizing MPI\_SendRecv. The code can be found in the appendix for this section.

We get the following graph from the measurements which were performed in the same way as for the previous program:

Figure 2: Ping Pong with MPI\_SendRecv: Number of bytes sent vs. average time taken from 1000 pairs of send / receive. 5 runs shown for each size as scatter plot. Mean of these 5 runs shown as line. Blue small fit includes all data points up to 32768 bytes, blue large from there. Red small fit includes all data points up to 32768 bytes, red large from there.

We get the following fits and Rš values for the runs:

Run Type	Data Size	Fit Equation	Rš Value
Single Node	Small (<=32768)	$3.51 \times 10^{-7} \cdot x + 1.19 \times 10^{-3}$	0.98
Single Node	Large (>= $32768$ )	$1.69 \times 10^{-7} \cdot x + 4.00 \times 10^{-3}$	1.00
Two Node	Small (<=32768)	$6.65 \times 10^{-7} \cdot x + 9.47 \times 10^{-4}$	0.98
Two Node	Large (>= $32768$ )	$1.66 \times 10^{-7} \cdot x + 4.93 \times 10^{-3}$	1.00

Table 2: Fit Equations and Rš Values for Single Node and Two Node Runs

#### TODO: Further analysis needed?

#### 0.b) MM-product

After an introduction of the matrix-matrix multiplication code in the next section, the measured speedups are discussed in the subsequent section.

#### Explanation of the code

For this excercise I've used the template provided in the assignment sheet as a base to develop my parallel implementation for a matrix-matrix multiplication. The code can be found in the appendix for this section.

The porgam can be run either in sequential (default) or parallel mode (parallel as a command line argument). For the sequential version, the code is practically unchanged and just refactored into a function for timing purposes. The parallel version is more complex and works as explained bellow:

First, rank 0 computes a sequential reference solution. Then rank 0 distributes the matrices in the following way in splitwork:

- Matrix A is split row-wise by dividing the number of rows by the number of nodes.
- The first worker (=rank 1) gets the most rows starting from row 0: total\_rows (nr\_workers 1)  $\cdot floor(\frac{total_rows}{nr_workers})$ .
- All other workers and the master (= rank 0) get the same number of rows:  $floor(\frac{\text{total\_rows}}{\text{nr workers}})$ .
- The master copies the corresponding rows of matrix A and the whole transposed matrix B\* into a buffer (for details on MM\_input buffer see bellow) for each worker and sends them off using MPI\_ISend.
- The workers receive the data using MPI\_Recv and then compute their part of the matrix product and send only the rows of the result matrix back to the master using MPI\_Send.
- In the meanwhile the master computes its part of the matrix product.
- Using MPI\_Waitall the master waits for all data to be sent to the workers and only afterwards calls MPI\_Recv to gather the results from the workers.
- Finally all results are gathered by the master in the result matrix.

Assume we have a 5x5 matrix A and 2 workers (rank 1 and rank 2) and master (rank 0). The partitioning is done row-wise as follows:

# Partitioning Example

$$A = \begin{pmatrix} a_{11} & a_{12} & a_{13} & a_{14} & a_{15} \\ a_{21} & a_{22} & a_{23} & a_{24} & a_{25} \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} \\ a_{41} & a_{42} & a_{43} & a_{44} & a_{45} \\ a_{51} & a_{52} & a_{53} & a_{54} & a_{55} \end{pmatrix} \rightarrow \begin{pmatrix} \text{Worker 1} \\ \text{Worker 1} \\ \text{Worker 1} \\ \text{Master} \\ \text{Master} \end{pmatrix}$$

- Rank 0 (Master): Rows 4 and 5 (last two rows)
- Rank 1 (Worker 1): Rows 1 to 3 (first three rows) Worker 1 always gets the most rows

This partitioning can be visually represented as:

Master (rank 0): 
$$\begin{pmatrix} a_{41} & a_{42} & a_{43} & a_{44} & a_{45} \\ a_{51} & a_{52} & a_{53} & a_{54} & a_{55} \end{pmatrix}$$
Worker 1 (rank 1): 
$$\begin{pmatrix} a_{11} & a_{12} & a_{13} & a_{14} & a_{15} \\ a_{21} & a_{22} & a_{23} & a_{24} & a_{25} \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} \end{pmatrix}$$

Each worker computes its part of the matrix product, and the master gathers the results at the end and compiles them into the final matrix.

The MM\_input buffer is used to store the rows of matrix A and the whole matrix B for each worker. It is implemented using a simple struct:

```
typedef struct MM_input {
    size_t rows;
double *a;
double *b;
} MM_input;
```

\*[Optimization] Note on transposed matrix B: It is usually beneficial from a cache perspective to index arrays sequentially or in a row-major order. However, in the matrix-matrix multiplication, we access the elements of matrix B in a column-wise order. This leads to cache misses and is not optimal. To mitigate this, we can transpose matrix B and then access it in a row-wise order. This is done in the code by the master before sending the data to the workers.

#### Discussion of the speedups

The code was run on Delft's cluster with 1, 2, 4, 8, 16, 24, 32, 48, and 64 nodes. For the experiments the matrix size of A and B was set to  $2000 \times 2000$ . This means that the program has to evaluate 2000 multiplications and 1999 additions for each element of the resulting matrix C. In total this results in  $\approx 2000^3 = 8 \times 10^9$  operations. The command looked similar to the following for the different node counts:

srun -n 48 --mem-per-cpu=4GB --time=00:02:00 ./MM.out parallel

For this experiment, the execution time was measured and the speedup was calculated. The results are shown in Table 3 and Figure 3.

CPU Count	Execution Time / s	Approx. Speedup
1	47.11	1.0
2	10.26	4.6
4	10.30	4.6
8	5.20	9.1
16	2.97	15.9
24	2.54	18.5
32	2.29	20.6
48	2.98	15.8
64	1.72	27.4

Table 3: Execution Time vs CPU Count

Figure 3: Speedup vs CPU Count Black  $\times$  marks the average of the rerun for n=48.

**Note:** The speedup is calculated as  $S = \frac{T_1}{T_p}$ , where  $T_1$  is the execution time on 1 node and  $T_p$  is the execution time on p nodes.

#### Discussion:

As one can cleary discern from the data in Table 3 and Figure 3, the speedup increases with the number of nodes (with the exception of n = 48). This is expected as the more nodes we have, the more work can be done in

parallel. However, the speedup is not linear. This is due to the overhead of communication between the nodes. The more nodes we have, the more communication is needed, and this overhead increases. This is especially visible in the data for n = 48. Here the speedup is lower than for n = 32. For this run the communication didn't went as smooth as for the other runs. This can potentially be attributed to the fact that one (or more) of the nodes or the network was under heavy load during this task.

[Further investigation] After observing this slower speed for the n=48, I reran the tests multiple times and got a runtime of around 1.9s which was to be expected initially. Therefore, this one run is an odd one out, most likely due to the reasons mentioned above! I've also added the averaged data of the reruns as a datapoint in Figure 3.

Another interesting fact can be seen when comparing the time taken for n = 1 and n = 2. They don't at all scale with the expected factor of 2. This is could be due to the fact, that the resource management system prefers runs with multiple nodes instead of a single node (= sequential).

Additional notes: The flag <code>-mem-per-cpu=<#>GB</code> was set depending on the number of nodes used. For 1-24 nodes 8GB was used, for 32-48 nodes 4GB, and for 64 nodes 3GB. This had to be done to comply with QOS policy on the cluster.

TODO: Data locality?

# 1 Poisson solver

In this section of the lab report, we will dicuss a prallel implementation of the Poisson solver. The Poisson solver is a numerical method used to solve the Poisson equation, which is a partial differential equation that is useful in many areas of physics.

Note: For local testing and development I'll run the code with mpirun instead of the srun command on the cluster.

#### 1.1 Building a parallel Poisson solver

For the first part of the exercise we follow the steps lined out in the assignment sheet. I'll comment on the steps 1 through 10 and related questions bellow. The finished implementation can be found in the appendix for this section.

1. **Step:** After adding MPI\_Init and MPI\_Finalize, we can run the program with multiple processes. We can see that the program runs with 4 processes in Figure 4 via the quadrupeled output.

```
etschgi1@Deep-Thought:~/REPOS/HPC/01_lab1/src$ mpirun -np 4 ./mpi.out
Number of iterations : 2355
Number of iterations : 2355
Elapsed processortime: 0.133189 s
Number of iterations : 2355
Elapsed processortime: 0.134150 s
Elapsed processortime: 0.134474 s
Elapsed processortime: 0.135356 s
```

Figure 4: MPI Poisson after Step 1 - Running with 4 processes

2. **Step:** To see which process is doing what, I included the rank of the process for the print statements as shown in Figure 5.

Figure 5: MPI\_Poisson after Step 2 - Running with 4 processes

3. **Step:** Next we define wtime as a global double and replace the four utility timing functions with the ones given on Brightspace. A quick verification as shown in Figure 6 shows that the program still runs as expected.

Figure 6: MPI Poisson after Step 3 - Running with 4 processes

- 4. **Step:** Next we check if two processes indeed give the same output. Both need 2355 iterations to converge and the diff command returned no output, which means that the files content is identical.
- 5. **Step:** Now only the process with rank 0 will read data from files and subsequently broadcast it to the others. Testing this again with 2 processes, we see an empty diff of the output files and the same number of iterations needed to converge.

6. **Step:** We create a cartesian grid of processes using MPI\_Cart\_create and use MPI\_Cart\_shift to find the neighbors of each process. We can see that the neighbors are correctly identified in Figure 7.

```
(0) (x,y)=(0,0)

(0) top 1, right -2, bottom -2, left 2

(1) (x,y)=(0,1)

(1) top -2, right -2, bottom 0, left 3

(2) (x,y)=(1,0)

(2) top 3, right 0, bottom -2, left -2

(3) (x,y)=(1,1)

(3) top -2, right 1, bottom 2, left -2
```

Figure 7: MPI\_Poisson after Step 6 - Running with 4 processes on a 2x2 grid

When there is no neighbor in a certain direction, -2 (or MPI\_PROC\_NULL) is returned.

7. **Step:** We overhaul the setup to get a proper local grid for each process. Furthermore, we only save the relevant source fields in the local grid for each process.

With for instance 3 processes you should see that 1 or 2 processes do not do any iteration. Do you understand why?

If we have a look at the input file we see that there are only 3 source fields in the grid. This means that the process that does not have a source field in its local grid will not do any iterations (or only 1). Therefore, if we have 3 processes and the distribution of source fields as given in the input file only 1 process will do iterations if processes are ordered in x-direction and 2 if ordered in y-direction. From this we can conclude that indeed all processes have different local grids and perform different calculations.

```
• etschgi1@Deep-Thought:~/REPOS/HPC/02_lab1/src$ mpirun -np 3 ./mpi.out 3 1
(0) (x,y)=(0,0)
(0) top -2, right -2, bottom -2, left 1
(1) (x,y)=(1,0)
(2) (x,y)=(2,0)
(3) Number of iterations: 1
(2) Elapsed Wtime 0.000618 s (95.3% CPU)
(3) Elapsed Wtime 0.000477 s (95.2% CPU)
(4) Number of iterations: 695
(5) Elapsed Wtime 0.017636 s (95.3% CPU)
(6) Elapsed Wtime 0.017636 s (95.3% CPU)
(7) Elapsed Wtime 0.017636 s (95.3% CPU)
(8) Elapsed Wtime 0.017636 s (95.3% CPU)
(9) Elapsed Wtime 0.017636 s (95.3% CPU)
(10) Elapsed Wtime 0.017636 s (95.3% CPU)
(21) Elapsed Wtime 0.017636 s (95.3% CPU)
(22) Elapsed Wtime 0.017636 s (95.3% CPU)
(23) Elapsed Wtime 0.017636 s (95.3% CPU)
(24) Elapsed Wtime 0.017636 s (95.3% CPU)
(25) Elapsed Wtime 0.017636 s (95.3% CPU)
```

Figure 8: MPI\_Poisson after Step 7 - Running with 3 processes on a 3x1 (left) vs. 1x3 (right) grid For the 3x1 grid, only rank 1 does iterations (> 1), for the 1x3 grid, ranks 0 and 2 do iterations (> 1).

- 8. **Step:** After defining and committing two special datatypes for vertical and horizontal communication, we setup the communication logic to exchange the boundary values between the processes. We call our Exchange\_Borders function after each iteration (for both red / black grid points). Now we face the problem in which some processes may stop instantly (no source in their local grid). They will not supply any data to their neighbors, which will cause the program to hang. We shall fix this in the next step.
- 9. **Step:** Finally we need to implement the logic to check for convergence (in a global sense). We do this by using a MPI\_Allreduce call with the MPI\_MAX operation. This way we aggregate all deltas and choose the biggest one for the global delta which we use in the while-loop-condition to check for convergence. We can see that the program now runs as expected in Figure 9.

```
(0) (x,y)=(0,0)

(0) top -1, right 2, bottom 1, left -1

(1) (x,y)=(0,1)

(1) top 0, right 3, bottom -1, left -1

(2) (x,y)=(1,0)

(2) top -1, right -1, bottom 3, left 0

(3) (x,y)=(1,1)

(3) top 2, right -1, bottom -1, left 1

(0) Number of iterations : 2355

(1) Number of iterations : 2355

(2) Number of iterations : 2355

(3) Number of iterations : 2355

(1) Elapsed Wtime 0.287549 s (99.9% CPU)

(2) Elapsed Wtime 0.287537 s (100.0% CPU)

(3) Elapsed Wtime 0.287537 s (99.9% CPU)

(6) Elapsed Wtime 0.295957 s (99.9% CPU)
```

Figure 9: MPI\_Poisson after Step 9 - Running with 4 processes on a 2x2 grid

Note that this run in Figure 9 was done with another pc and another MPI implementation. Therefore, we see -1 for cells without a neighbor! However, other than that cosmetic difference it has no impact on the programm.

10. **Step:** Now we only have to fix two remaining things. First we have to make sure that each process uses the right global coordinates for the output file in the end. Therefore, we change the function a bit to include the specific x-/y-offset for each processor. The second thing is the potential problem, that different processors might start with different (red/black) parities. In order to accomplish a global parity we simply have to change the calculation in the if in Do\_Step from

```
if ((x + y) % 2 == parity && source[x][y] != 1)

to

if ((x + offset[X_DIR] + y + offset[Y_DIR]) % 2 == parity && source[x][y] != 1)
```

this guarantees that during a given iteration all processors are using the same parity.

This just leaves one question open: Are the results acutally the same?

Checking the output files of the MPI-implementation with the sequential reference indeed shows identical numerical values for the calculated points. Furthermore, the needed iteration count is also identical which isn't a big surprise, given that the two programms perform the exact same calculation steps.

#### 1.2 Exercises, modifications, and performance aspects

For this subsection we'll define the following shorthand notation:

TODO: RUN ON DELFT BLUE!!!

pt = 414 means 4 processors in a  $1 \times 4$  topology.

n:	the number of iterations
<i>g</i> :	gridsize
t:	time needed in seconds
pt:	processor topology in form $pxy$ , where:
p:	number of processors used
x:	number of processors in x-direction
y:	number of processors in y-direction

Table 4: Notation for this section

#### Note on different Versions:

For the following exercises the implementation will be slightly adapted to measure different performance aspects. To facilitate this, we will use defines to switch between different versions of the code at compile time. The final version of the poissonsolver can be found in the appendix for this section.

#### Note on long scheduling times and work-arounds:

Delft Blue is especially bussy and wait times for jobs can be well over 30 minutes regularly. As we make use of

these resources extensively in this lab, I've created sbatch scripts which run mutliple configurations at once. For development of the tests and postprocessing I'll make use of my local machine. As discussed with the tutor of this lab, for some exercises a local run is sufficient to get the desiered insights (e.g. subsubsection 1.2.2 to find the optimal omega). I'll also note this in the respective subsections.

#### 1.2.1 Over-relaxation (SOR)

We start of by rewriting the Do\_Step routine to facilitate SOR updates. Furthermore, we need  $h^2$ , the grid spacing (which is 1 in our case) and the relaxation parameter  $\omega$  to calculate the updated values. A quick local test shows a speedup of roughly a factor of 10. More systematic tests will be done in the next section.

#### 1.2.2 Optimal $\omega$ for 4 proc. on a 4x1 grid

With the power of a little python scripting we can easily test different values for  $\omega$  and plot the results as seen in Figure 10. This test was performed locally as the results are not dependent on processors because the number of iterations needed for convergence is the same for different configurations and only depends on the algorithm and the specific problem.

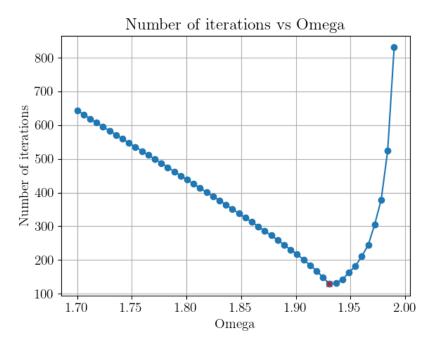

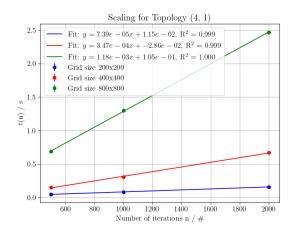

Figure 10: Optimal  $\omega$  for 4 processors on a 4x1 grid

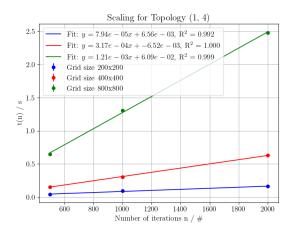

We find that the optimal  $\omega$  is at about 1.93 for this setup with only 129 iterations. This constitutes a speedup of about 1825% compared to the sequential implementation.

**N.B.:** If not stated otherwise, we will use  $\omega = 1.93$  for the following exercises.

#### 1.2.3 Scaling behavior with larger grids

This investigation is carried out twice: Once with a  $4 \times 1$  topology (as in the previous section) and once with a  $2 \times 2$  topology. We use grid sizes of  $10 \times 10$ ,  $25 \times 25$ ,  $50 \times 50$ ,  $100 \times 100$ ,  $200 \times 200$ ,  $400 \times 400$ ,  $800 \times 800$  and  $1600 \times 1600$  and set  $\omega = 1.95$  for all runs. The results are shown in Figure 11.

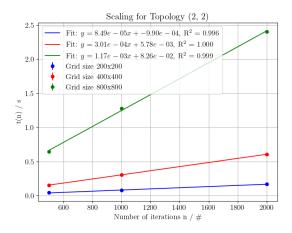

Figure 11: Scaling behavior of the Poisson solver with different grid sizes and processor topologies

As seen by the high  $R^2$  values in the plots, the scaling behavior is very close to linear. We obtain the following scaling factors for the different grid sizes and topologies from the linear fits:

Topology	Gridsize	$\alpha$	β
$4 \times 1$	$200 \times 200$	$1.15 \cdot 10^{-2}$	$7.39 \cdot 10^{-5}$
$4 \times 1$	$400 \times 400$	$-2.86 \cdot 10^{-2}$	$3.47 \cdot 10^{-4}$
$4 \times 1$	$800 \times 800$	$1.05 \cdot 10^{-1}$	$1.18 \cdot 10^{-3}$
$1 \times 4$	$200 \times 200$	$6.56 \cdot 10^{-3}$	$7.94 \cdot 10^{-5}$
$1 \times 4$	$400 \times 400$	$-6.52 \cdot 10^{-3}$	$3.17 \cdot 10^{-4}$
$1 \times 4$	$800 \times 800$	$6.09 \cdot 10^{-2}$	$1.21 \cdot 10^{-3}$
$2 \times 2$	$200 \times 200$	$-9.90 \cdot 10^{-4}$	$8.49 \cdot 10^{-5}$
$2 \times 2$	$400 \times 400$	$5.78 \cdot 10^{-3}$	$3.01 \cdot 10^{-4}$
$2 \times 2$	$800 \times 800$	$8.26 \cdot 10^{-2}$	$1.17 \cdot 10^{-3}$

Table 5: Scaling factors for different processor topologies for the Poisson solver Using:  $t(n) = \alpha + \beta \cdot n$  as a model

#### What can you conclude from the scaling behavior?

We see that the scaling behavior is very close to linear for both topologies. This means that the parallel implementation scales as expected with the number of grid points.

If we compare the scaling factors  $(\beta)$  for the two topologies we see that the  $2 \times 2$  topology scales slightly better than the  $4 \times 1$  and  $1 \times 4$  topologies. This is not surprising, as the  $2 \times 2$  topology has a more balanced communication workload balance. In the  $2 \times 2$  topology every processor has two neighbors, while in the  $4 \times 1$  and  $1 \times 4$  topologies the processors at the ends only have one neighbor. This is a general trend: A topology which divides the grid into square / square-like parts will scale better than a topology which divides the grid

into long and thin parts.

In essence: We want to keep the communication between processors as balanced as possible to achieve the best scaling behavior. Scaling of different grid sizes:

We see that larger grids take longer for the same amount of iterations. This is also to be expected, as the number of grid points grows quadratically with the grid size. a  $400 \times 400$  grid has 4 times as many grid points as a  $200 \times 200$  grid and therefore takes roughly 4 times as long to calculate.

#### 1.2.4 Scaling behavior [Theory - no measurements]

If I could choose between a  $16 \times 1$ ,  $8 \times 2$ ,  $4 \times 4$ ,  $2 \times 8$ ,  $1 \times 16$  topology, I would choose the  $4 \times 4$  topology. This is because the  $4 \times 4$  topology has the most balanced communication workload balance, as detailed in the **Shining** in subsubsection 1.2.3.

#### 1.2.5 Iterations needed for convergence scaling

We investigate the number of iterations needed for convergence using the  $4 \times 1$  topology square grids with sidelength: 10, 25, 50, 100, 200, 400, 800, 1600. The results for different  $\omega$  are shown in Figure 12.

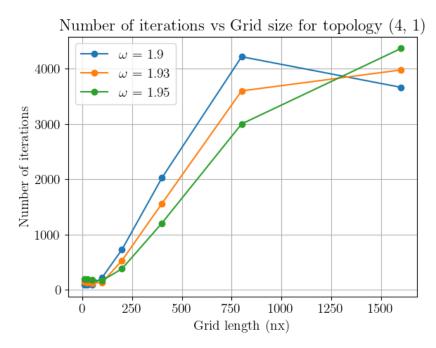

Figure 12: Iterations needed for convergence with different grid side lengths

We can clearly see that the number of iterations till convergence increases with the problem size. At first, I expected linear growth proportional to the number of gridpoints. However, it turns out that the number of iterations actually grow slower and in a square root like fashion. This can be seen by the linear behavior in the plot of grid-side length against iterations.

# Why is the number of iterations needed for convergence $\propto \sqrt{g}$ ?

Our poisson problem is a discretized system in 2D space. The condition number of the matrix we have to solve is proportional to the number of gridpoints in our system. SOR uses the spectral properties of the matrix to solve in a way such that the dominant error mode takes time proportional to the diameter of the domain to converge. This means it is proportional to  $\sqrt{g} = \sqrt{n_x \cdot n_y}$ .

#### Why does omega with the best performance change with the grid size?

As can be seen in Figure 12  $\omega=1.9$  beats the other two values for very small and the largest gridsize. For different gridsizes we get differently sized matrices we have to solve. SOR overrelaxes high-frequency errors and underrelaxes low-frequency errors (the later for stability). The optimal  $\omega$  is therefore dependent on the gridsize and the error modes present in the system. In our current example, it might be that  $\omega=1.9$  is a good compromise for the grid sizes we are looking at.

#### 1.2.6 Error as a function of the iteration number

With the same  $4 \times 1$  topology and grid sizes of  $800 \times 800$  the error for 15000 iterations is tracked using  $\omega = 1.93$ . The results are shown in Figure 13.

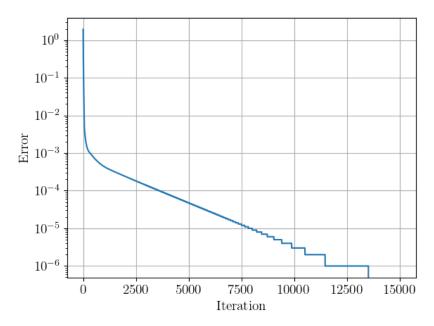

Figure 13: Error as a function of the iteration number

At first the error decreases rapidly in the first few iterations to about  $10^{-3}$  (logarithmic scale!). After that the error decreases more slowly until it is below floating point precision. **Note:** All calculations are done using double precision floating point numbers and only the error recording was done using single precision which leaves the step-like artifacts in the plot.

#### 1.2.7 Optional - Gain performance by reducing MPI\_Allreduce calls

The last subsection showed us that the error reduces monotonically. We might be able to save some time by leaving out some checks and maybe check the global error every 10th or 100th iteration only.

First, we should benchmark if it is at all wise to optimize here, by measuring how long the MPI\_Allreduce call takes. We can do this by measuring the time needed for the MPI\_Allreduce call in the Do\_Step function and summing up to get the total time spent in MPI\_Allreduce calls.

We again solve with a  $4 \times 1$  topology,  $\omega = 1.93$  and a  $800 \times 800$  grid: It takes roughly 20 seconds of which the processors spend around 1 - 2 seconds in the MPI\_Allreduce call. This is a significant amount of time  $((7.0 \pm 0.4)\%)$ . This means we would save some time by reducing the number of MPI\_Allreduce calls and calculating 9 (0.25%) of total) more iterations wouldn't hurt us too bad because it takes 3601 to converge!

We run the program three times with MPI\_Allreduce calls every 1, 10 and 100 iterations and get the speedups in MPI\_Allreduce calls as shown in Table 6.

Iterations	MPI_Allreduce - speedup (factor)	calculated overall speedup (%)
1	1.00	0
10	$6.0 \pm 2.0$	$5.9 \pm 0.5$
100	$62 \pm 6$	$6.9 \pm 0.4$

Table 6: Speedup in MPI\_Allreduce calls for different iteration counts and calculated overall speedup (%)

As can be clearly seen from the table we can gain around 6% using MPI\_Allreduce calls every 10 iterations and around 7% using MPI\_Allreduce calls every 100 iterations. This is a significant speedup for a very small change in the code.

**Note:** The speedup is calculated to account for fluctuations in the runtime of the program, due to other processes running on the same machine / cluster.

#### 1.2.8 Reduce border communication

Another way to reduce communication overhead is to reduce the number of border exchanges. To investigate if this yields a speedup we run the program on a  $4 \times 1$  topology,  $\omega = 1.93$  and different grid sizes and track the iterations and time as seen in Figure 14.

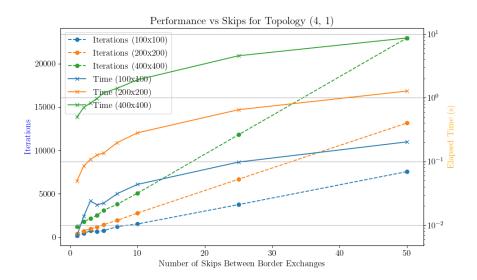

Figure 14: Speedup by reducing border exchanges

Running the with different numbers of skipped border exchanges naturally slows down convergence, meaning we need more iterations to reach the same error. For all tested grid sizes the initial SOR version without skipping border exchanges has the fewest iterations needed to convergence and also the fastes runtime.

#### What can you conclude from the results?

We can conclude that reducing the number of border exchanges does not yield a speedup. The reason for this is that we have to calculate more iterations to converge to the solution which outweighs the gains from reduced communication overhead. Interestingly, for the  $100 \times 100$  grid there exists a local minimum in time at 4 skipped border exchanges compared to 3 skipped. This is likely due to our source field distribution and thus specific to our problem.

#### 1.2.9 Optimize Do\_Step loop

In Do\_Step we iterate over the whole grid but only update one of the two parities at a time. This means we can split the loop into two loops, one for each parity. We start out with something like this:

```
for (x = 1; x < dim[X_DIR] - 1; x++){
    for (y = 1; y < dim[Y_DIR] - 1; y++){
        if ((x + offset[X_DIR] + y + offset[Y_DIR]) % 2 == parity && source[x][y] != 1){
        ...</pre>
```

and we change it to:

```
int start_y;
for (x = 1; x < dim[X_DIR] - 1; x++){
    start_y = ((1 + x + offset[X_DIR] + offset[Y_DIR]) % 2 == parity) ? 1 : 2;
for (y = start_y; y < dim[Y_DIR] - 1; y += 2){
    if (source[x][y] != 1){
        ...</pre>
```

The basic idea is to avoid y-coordinates which are not in the parity we are currently updating. We measure 10 runs for a  $800 \times 800$  grid and a  $4 \times 1$  topology with  $\omega = 1.93$  and get the following times:

```
t_{\text{no\_improvements}} = (5.59 \pm 0.05) \,\text{s} and t_{\text{loop\_improvements}} = (4.64 \pm 0.07) \,\text{s}
```

So we get a minimal speedup of about 17% by optimizing the loop which is a enormous speedup for such a small change.

#### Why does this make such a difference

The reason for this is that we avoid unnecessary looping and if statements. This means that we have less overhead in the loop and can therefore calculate faster by skipping the unnecessary loop entries.

#### 1.2.10 Optional - Time spent within Exchange\_Borders

We can measure the time spent in Exchange\_Borders by adding a timer to the function. We run the program with  $\omega = 1.93$  and different topologies and grid sizes and get the results shown in Figure 15.

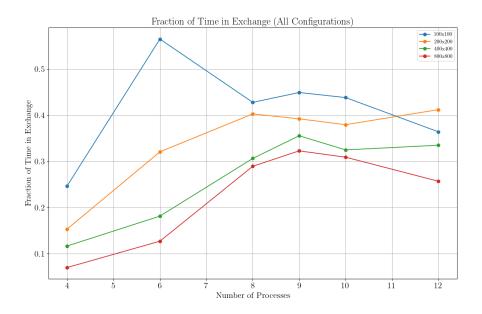

Figure 15: Fraction of total time spent in Exchange\_Borders

As we can clearly see, the time spent in Exchange\_Borders is initially smaller and grows with processor count. The curves are generally shifted downward for larger gridssizes.

#### Interpretation:

One would expect larger grid sizes to be more computationally expensive and we have already established that iterations take longer the bigger the grid. Communication obviously also takes longer for a larger grid because we have more data to sent. However, the circumference of a square grows linearly, while the area grows quadratically. The quadratic growth of the area is the reason for the downward shift in the curves for larger grid sizes because the communication overhead grows slower than the computational overhead for larger grids.

#### When is the time spent in Exchange\_Borders significant / comparable to computation?

As can be seen in Figure 15 the time spent in Exchange\_Borders is significant for all grid sizes from the start (between 5 and 25%). Thereafter it grows to around 30% to 45% for 9 processors. This means that the time spent in Exchange\_Borders is significant for all grid sizes and processor counts, but especially as the processor count grows.

#### 1.2.11 Latency and bandwith in Exchange\_Borders

We use the configurations from subsubsection 1.2.3:  $4 \times 1$ ,  $2 \times 2$  and  $3 \times 3$  topologies with grid sizes of  $200 \times 200$ ,  $400 \times 400$  and  $800 \times 800$  and  $\omega = 1.95$ . We obtain the results in Table 7.

Table 7: Metrics for  ${\tt Exchange\_Borders}$  latency and bandwith

Topology	Grid Size	Latency (ms)	Latency (%)	Bandwidth $(B s^{-1})$	Total Data (B)
4x1	200x200	$370 \pm 44$	6.6	447314206	135548032
4x1	400x400	$328 \pm 39$	6.0	511 267 773	135548032
4x1	800x800	$401 \pm 38$	7.1	390446955	135548032
2x2	200x200	$346 \pm 83$	6.2	426689734	108546432
2x2	400x400	$281 \pm 74$	5.2	576865986	108546432
2x2	800x800	$288 \pm 71$	5.3	558562482	108546432
3x3	200x200	$1054 \pm 204$	25.2	78386044	72364288
3x3	400x400	$1147 \pm 229$	27.6	81 623 075	72364288
3x3	800x800	$1082 \pm 148$	26.7	60 819 112	72 499 296

#### **Interpretation:**

As can be seen the latency is more or less comparable between the  $4 \times 1$  and  $2 \times 2$  topologies. The  $3 \times 3$  topology has a significantly higher latency. This is due to the fact that the  $3 \times 3$  topology has more neighbors to communicate with.

#### 1.2.12 Exchange Border potential improvements

Indeed we communicate twice as much as we need after each Do\_Step call. We shall analyze this considering the following points:

- address of the first point to exchange: This depends on the parity of the processor. It is simply the first or second point in the grid depending on the parity (leaving out the edge case where the processor only has one data-point).
- the number of points to exchange: This normally is the number of points in the grid minus ghost cells divided by two. However, this may change if there is an odd number of points in the grid (then we have to exchange one more or one less point).
- the number of points in between grid points that have to be exchanged: The stride of the data will change. Currently we exchange every point for one direction and every dim[Y\_DIR]-th point for the other direction. This can be optimized to exchange every second point in one direction and every second dim[Y\_DIR]-th point in the other direction.

#### Is it worth it?

For smaller gridsizes it is not worth it to optimize the border exchange. The time spent in the border exchange might be significant in relative terms, but the absolute time is still small. For larger gridsizes it might be worth it to optimize the border exchange. As we have seen, this becomes more significant as the processor count and gridsizes grow. For our current problem and similarly sized problems the effort put into optimizing the border exchange is certainly not worth it.

# 2 Finite elements simulation

We will now shift our focus to a more general grid which is based on triangulation. In this section we will compare our parallel implementation from the previous section and disect the differences and similarities. For that reason we shall use the same sources in our grid as given in sources.dat.

Note that the sections for the exercises will be labeled as (2.1, 2.2, 2.3, ...) corresponding to exercises (4.1, 4.2, 4.3, ...) in the lab manual.

#### 2.1 Code understanding & Exchange\_Borders

The first step is to read through the code in **MPI\_Fempois.c** and to understand it. Furthermore, we have to implement the **Exchange\_Borders** function for which only a skeleton is given. The function should exchange the border values of the local grid with the neighboring processes.

The implementation of this function is quite straight forward. We only have to loop over all the neighbors of a process and send out the border values and receive the border values from the neighbors. The function is implemented as follows:

# 2.2 Time benchmarking

Next we turn our attention to timing of different sections in the code. We have to measure:

- Time spent in computation
- Time spent exchanging information with neighbors
- Time spent doing global communication
- Idle time

We setup the following variable to measure / deduce the time spent in the different sections:

```
double total_time = 0.0;
double exchange_time_neighbors = 0.0;
double exchange_time_global = 0.0;
double compute_time = 0.0;
```

We will measure the time spent in computations by timing the solve function and subtracting the time spent in the MPI\_Allreduce calls. The time spent in the MPI\_Allreduce calls is the time spent in global communication. The time spent in exchanging information with neighbors is the time spent in the Exchange\_Borders function. Finally, the idle time can be determined by summing up the differences between the cores total time and the slowest cores total time. Note that this way of calculating the idle time is an approximation since it is assumed that the slowest core doesn't have any idle time. However, I've discussed this with the TA and he said that this is a valid way of calculating the idle time for this exercise.

The commandline output for runs is as shown in Figure 16 for an example run:

```
(2) - Exchange time (neighbors): 0.007183
(2) - Exchange time (global): 0.002372
(2) - Sum of times (compute + exchange (global & local)): 0.062241
(2) - Total time: 0.069645
(0) - Total time: 0.069800
(1) - Compute time: 0.051027
(1) - Exchange time (neighbors): 0.005517
(1) - Exchange time (global): 0.004273
(1) - Sum of times (compute + exchange (global & local)): 0.060816
(1) - Total time: 0.069416
(3) - Compute time: 0.051977
(3) - Exchange time (neighbors): 0.006824
(3) - Exchange time (global): 0.003341
(3) - Sum of times (compute + exchange (global & local)): 0.062142
(3) - Total time: 0.069399
```

Figure 16: Timing for the different sections.

(x) ... denotes the process rank

Compute time ... time spent in the solve function only on computing

Exchange time (neighbors) ... time spent in Exchange\_Borders

Exchange time (neighbors) ... time spent in MPI\_Allreduce calls

Sum of times ... total time spent in compute and communication (excluding setup / idle time)

Total time ... total time spent in the program

The <u>idle time</u> is calculated as denoted above and therefore not shown in the output in Figure 16. We get the following results in Table 8:

Top.	Grid Size	Total (avg)	Comp. (avg)	Ex. Neighb. (avg)	Ex. Global (avg)	Idle (avg)
1x4	100x100	57.0	32.5	5.6	13.3	0.6
1x4	200x200	383.6	289.1	13.3	48.8	1.7
1x4	400x400	2239.5	1886.9	22.2	206.1	11.6
2x2	100x100	57.4	33.6	4.7	8.7	4.5
2x2	200x200	348.3	266.6	15.5	35.0	4.0
2x2	400x400	2313.2	1959.8	26.4	204.0	11.5

Table 8: Rank averaged time benchmark for different grid sizes and topologies.

All times are in milliseconds.

We see that the total time is comparable between the two topologies for all grid sizes. Furthermore, the total runtime also increases non-surprisingly with the gridsize.

# Why does it increase faster than linearly?

One could expect, that the grid with  $200 \times 200$  elements would take 4 times as long as the grid with  $100 \times 100$  elements. However, the runtime roughly 7 times longer. This happens because additionally to the higher number of grid points the algorithm also takes longer (more iterations) to converge.

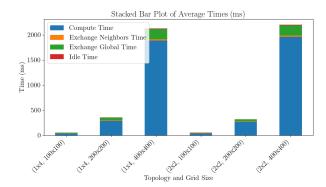

#### Analysis of the different times

To get a better grasp on the data a stacked bar plot, as shown in Figure 17, is created. We immediately see that the bulk of the time is spent on computing the solution. The second biggest contributor is the global exchange time, followed by local exchange time and idle time (except for  $2 \times 2$  on the  $100 \times 100$  grid).

That computation takes up the biggest part of the time is of non surprise especially on the bigger grids this is to be expected. Rather surprisingly the global excannge time comes in second. This begs the question why two lines of the form:

```
MPI_Allreduce(..., ..., 1, MPI_DOUBLE, MPI_SUM, grid_comm);
```

take up this much time. This actually comes down to masked idle time. While the operation itself only sums up the values of 4 double, the operation is blocking and therefore the other cores have to wait for the slowest core to finish. If we look back at the definition of idle time, we defined it as the difference of the total time of the slowest core and the total time of the current core. However, as stated above, this does not take waiting time in MPI calls (like MPI\_Allreduce) into account. Certainly, this explains now that the global exchange time is high, because every core has to wait for the others to synchronize to compute the MPI\_Allreduce.

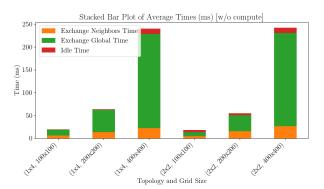

Figure 17: Scaling behavior of the Poisson solver with different grid sizes and processor topologies

#### 2.3 Data exchange amount

This section is about the amount of data exchanged each iteration among one process with all its neighbors. We assume a uniformly triangulated grid which is partitioned stripe-wise and distribution over P processes. Furthermore, we assume that each process has to send the same amount of data. Indeed, this is not generally the case but for examples with periodic boundary conditions this is for example a valid assumption.

Now we see that every process has to communicate with 2d neighbors, where d is the dimension of the grid, under our assumptions there are 2 neighboring processes. With the assumption of a  $n^2$  grid, our process communicates n values with each of these neighbors. For striped partitioning we get:

Data exchanged per Process = 2n

or in total:

Data exchanged =  $2n \cdot P$ 

Let's check for the extreme case  $1000 \times 1000$  grid and P = 500 processes. We get:

 $Data\ exchanged = 2 \cdot 1000 \cdot 500 = 1000000$ 

Which is the same amount of data as there are datapoints. This makes sense because every process has to communicate the top row upwards and the bottom row downwards.

Note, that we could even do worse if we assigned every process a single row. In this case every process would have to communicate the same data upward and downward. This would result in a data exchange of  $2 \cdot 1000 \cdot 1000 = 2000000$  which is double the amount of data as there are datapoints.

For a box partitioning a process has to communicate  $n/\sqrt{P}$  (assuming divisibility with all neighbors) with each of its 4 neighbors. We get:

Data exchanged per Process =  $4 \cdot n/\sqrt{P}$ 

or in total:

Data exchanged = 
$$4 \cdot n \cdot \sqrt{P}$$

This means that a striped partitioning is less efficient compared to a boxed partitioning starting from P = 4, as can be seen in Figure 18.

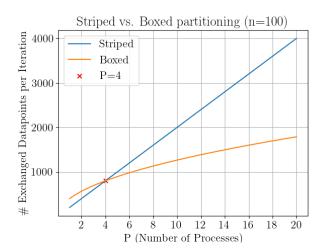

Figure 18: Striped vs. Boxed partitioning on a  $100 \times 100$  grid using P processors.

#### 2.4 Unbalanced communication

In the last section we assumed that every process has to communicate with the same amount of neighbors in our given scenario. That is actually not entierly true. There is an imbalance, even if just a small one. But where does this imbalance come from?

Let's take a look at a **uniformly triangulated grid** with P=4 processes. We assume that the grid is box-partitioned as given in Figure 19.

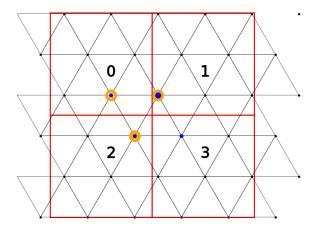

Figure 19: Box partitioning of a uniformly triangulated grid with P=4 processes. One point (big-blue) in 1 (and similarly in 3) has to communicate its value to 3 neighbors (small-blue). Another point (big-orange circle) in 2 (and similarly in 4) has to communicate its value to 2 neighbors (small-orange circles).

We see that the geometry of a given uniform triangulated grid leads to an imbalance in communication. This imbalance is usually not a big problem, especially for bigger grids with comparably small amounts of processors because only 2 points have to communicate with 3 neighbors. However, for smaller grids or proportionally high processor counts the imbalance is more significant.

Looking at a  $3\times3$  grid with P=9 processors, we see that the imbalance is more significant as shown in Figure 20.

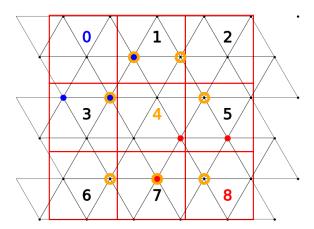

Figure 20: Box partitioning of a uniformly triangulated grid with P=9 processes.

Corner (0/8 - blue/red) processes have to communicate their values to 2 or 3 neighbors respectively (1 and 3 - blue or 4, 5 and 7 - red).

Central (4 - orange) processes have to communicate their value to 6 neighbors (1, 3, 5, 6, 7 and 8).

As we can see the imbalance comes from the partitioning geometry on the uniform triangulated grid. Because our processor grid is rectangular the results will always, in one way or another come out as shown in the schematic above.

For  $3 \times 3$  grid we have 4 corner processes which have to communicate with 2 or 3 neighbors and 1 central process which has to communicate with 6 neighbors. This is a significant imbalance and compared to the  $2 \times 2$  grid it is not negligible, because the central process has to communicate more than 2 extra points (whole edges of datapoints) to its neighbors.

#### 2.5 Estimates for computation $\equiv$ communication time

**N.B.** This section will use two different ways to estimate the equilibrium point.

Let's assume that we have 4 processes and want to estimate for which grid size the computation time is equal to the communication time.

One way to estimate this is by extrapolating from our measurements in Table 8 and find the point where the times are equal. Thereafter we can use this information to fit the side length of the grid to the computation time for the given time to find the grid size where the computation time is equal to the communication time. This process gives us a value of  $n \approx 79$  for the grid size as shown in Figure 21

We'll also estimate this equilibrium point for a  $1000 \times 1000$  grid. However, this time around we'll actually use a different way of calculating the number of Processes. We use the definitions from the lecture for stencil type computation:

- Computation time:  $T_{\rm S} = {\rm number\_ops} \cdot t_{\rm op} \sim 4t_{\rm op} \cdot n^2$  (for stencil type overall)
- Communication time:  $T_{\text{comm}} = \text{number\_comm} \cdot t_{\text{comm}} \sim 2n \cdot t_{\text{data}}$  (for stencil type overall)

Note that the definitions above apply for a single iteration and **one** processor!

We can calculate the time for communication from the data in Table 8 as follows:

$$t_{\rm data}(P) = \frac{t_{\rm global\_comm} + t_{\rm neighbor\_comm}}{2 \cdot n \cdot P \cdot \#_{\rm iterations}}$$

Similarly we can calculate the time for computation as follows:

$$t_{\rm op} = \frac{t_{\rm comp.}}{4 \cdot n^2 \cdot \#_{\rm iterations}}$$

Note that the later doesn't depend on the number of processes.

If we rearange for  $t_{\text{comp.}}$  and solve for n=1000 we get an approximate value of  $t_{\text{comp.}}\approx 29$  s. From this we want to solve for P in the  $t_{\text{data}}(P)$  using  $t_{\text{data}}(P)=29$  s.

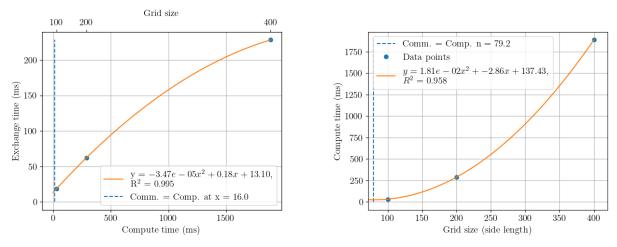

Figure 21: Fitting expected computation time  $\equiv$  communication time for 4 processes.

The matrix multiplication used the following code:

```
* FILE: mm.c
  * DESCRIPTION:
3
4
       This program calculates the product of matrix a[nra][nca] and b[nca][ncb],
       the result is stored in matrix c[nra][ncb].
5
      The max dimension of the matrix is constraint with static array
   *declaration, for a larger matrix you may consider dynamic allocation of the
   *arrays, but it makes a parallel code much more complicated (think of
   *communication), so this is only optional.
